## 1 Introduction

## 2 Overview of Group Design and Market Survey

### 2.1 Market Survey

Before the aircraft concept was developed, a thorough market survey was conducted, investigating aircraft that meet the size requirements for this design exercise, which are:

- The aircraft must fall into EASA Part-25 (for large aeroplanes, more significant than 5700kg,
- The aircraft must seat no more than 24 passengers.

Considering these two characteristics, twenty-three aircraft, a combination of turboprop-powered and jet-powered aircraft, were surveyed in an initial, brief investigation. This initial investigation can be seen in Figure 2.1 (Jane's Information Group, 2023).

**Figure 2.1**

C17					Jet		

As seen in Figure 2.1, the scope of the initial investigation was small, but its purpose was twofold:

1. To investigate if there is a relationship between aircraft weight and the selected engine type,
2. To investigate the relationship between aircraft's airfield performance and weight.

This investigation was successful. From the completed market survey, the design team was able to ascertain that, generally speaking, the lighter aircraft are powered by turboprops rather than jet engines, although exceptions do exist, such as the A400. Additionally, heavier aircraft tended to have worse airfield performance than their lighter counterparts; in this case, worse performance means longer takeoff and landing distances. At this point, the scope of the market survey became narrower but more in-depth, deciding to focus only on ten aircraft, which more closely aligned with a design objective in mind: to transport aid and supplies into disaster zones. Figures 2.2 to 2.5 show the second market survey conducted.

**Figure 2.2**

Figures 2.2 and 2.5 not only confirm the assertions made by the initial market survey but also expand upon them by providing more detailed information. This additional information helps the design team to spot gaps in the existing market; for example, there is no aircraft listed that operates at a short range (less than one thousand kilometers). Furthermore, aircraft such as the ATR-42, which has a very large payload weight (44kN), also has both a very long takeoff distance and landing distance.

This, therefore, became a primary design objective for the group's aircraft. The goal was to create an aircraft that could transport heavy loads over short distances while also landing and taking off from short, perhaps unconventional airfields.

## 2.2 Design Overview

The purpose of the aircraft designed in this project is to deliver aid and specialist crew to disaster zones following a natural incident or warfare. The aircraft achieves this by having a short range (one thousand kilometers) but a high payload weight (twenty-four kilo newtons). In addition, the aircraft is capable of taking off from short fields (three hundred and thirty meters long) and landing on fields just over one thousand meters long. Figure 2.6 shows the plan view of the aircraft.

**Figure 2.6**

*The planview of the aircraft designed.*

The aircraft has a high wing (aspect ratio 9) with engines mounted upon it. In addition, the wing is fitted with both flaps and slats to produce a maximum  $C_L$  of 2.3 when taking off, ensuring the aircraft can get off the ground quickly.

While the aircraft is primarily designed to transport cargo on pallets, the internals of the fuselage are very customisable. If need be, pallet-carrying capabilities can be replaced for people transportation in the event that evacuations are needed following a disaster. When transporting passengers, the aircraft is completely capable of providing a suitable environment onboard, with air mass flow rates exceeding the minimum required by EASA Part-25 in all categories.

In terms of certification, the aircraft is entirely compliant with EASA Part-25 in all aspects; the aircraft is completely balanced in all loading configurations, and it meets all the necessary requirements when operating with only one engine. For example, it is able to climb out of an airfield at  $1.53^\circ$ , when the minimum acceptable climb-out angle is  $1.38^\circ$ .

Finally, the aircraft's power-to-weight ratio and wing loading is very finely tuned as seen in Figure 2.7.

**Figure 2.7**

*The power to weight ratio vs wing loading of the aircraft.*

As the lines all intersect at a similar position, the aircraft's power-to-weight ratio can be confirmed as approximately  $17 \text{ W/N}$ , with a wing loading of around  $2500 \text{ N/m}^2$ . The fact that the lines all intersect relatively closely provides sufficient evidence that the aircraft will be both aptly powered and stable, with enough lift being generated by the wing.

Ultimately, the designed aircraft is not only compliant with EASA Part-25, but it is also able to perform its duties as a transport aircraft in very challenging conditions, thanks to its short field operations capabilities and large weight payload.

### 3 Primary Tasks

The following three tasks, initial weight estimation, centre of gravity and environmental control systems, were all the author's responsibility for this aircraft. As the

member of the team with primary responsibility, it was the author's duty to make the design decisions and justify them with calculations, ensuring that all parameters make both logical sense but also comply with EASA Part-25, the regulatory body that would eventually go on to certify this aircraft.

### **3.1 Initial Weight Estimation**

Once the aircraft concept had been completed and unanimously agreed to by the design team, the first task was to estimate the weights. As a reminder, the aircraft was designed to transport specialist cargo, such as medical supplies, and crew into disaster zones. To do this, the aircraft needs to:

1. Have a high payload weight fraction and,
2. Operate from short, improvised airfields.

Therefore, the aircraft must weigh as little as possible while generating as much lift as possible with its wings. The goal of this element of the design is to tackle the first of those two characteristics.

It is well known that there is a complex relationship between aircraft range and weight. Logically, two aircraft of identical design will need different amounts of fuel depending on the distance they intend to travel. Therefore, it was quickly decided that aircraft range would not be a factor of primary concern. The aircraft is designed to transport specialty cargo into areas in need of immediate help, and it would be exceptionally useful if help cannot arrive by other methods of transportation such as road, rail or sea. The aircraft only needs to operate relatively short distances to and from a central hub or distribution centre to deliver aid to a local population.

The following parameters must be known in order to complete the weight estimation:

1. Range (km)
2. Payload (Pax and Cargo)
3. Power to Weight (P/W) Ratio of the Engine (kW/kN)
4. Specific Fuel Capacity (SFC) of the Engine ((N/s)/kW)

## 5. Wing Aspect Ratio

## 6. Fuselage Diameter/Length

## 7. Weight per Pax (kg)

Since the aircraft aims to primarily deliver aid supplies rather than transport people, the parameters were slightly modified to account for pallets of cargo that are one cubic meter in size, each capable of carrying 500kg. In addition to the cargo, the aircraft still aims to transport a small number of passengers; this was decided to be seven people maximum.

The parameters related to the engine (P/W and SFC) were taken from known data for the engine selected to power the aircraft, specifically the Pratt and Whitney 127G. The mass of an average person was approximated to be 90kg, and the fuselage D/L was taken to be 0.13. The two parameters not yet discussed, aspect ratio and range, were the most changeable as the design process continued. In total, 10 different initial weight estimations were conducted, with different parameters, to settle on the most acceptable outcome, which will shortly be presented, but the final value for aspect ratio was taken to be 9, and range to be taken at 1000km (it was decided that this would be sufficient to transport supplies short distances into relief areas). Table 3.1 shows the final design values for weight estimation.

**Table 3.1**

*Final values for weight estimation*

Range		Payload		P/W	SFC	Aspect Ratio	D/L	Payload Masses	
km	Pax	Pallets	kW/kN	(N/s)kW				Pax (kg)	Pallets (kg)
1000	7	4	17.1	0.00076	9	0.13	90	500	

Before estimating the aircraft's weight, the fuselage's length, breadth and depth can be estimated by the following equations, where  $x_p$  is the number of passengers and  $x_c$  is the number of pallets (or crates):

$$Length = 10 + 0.237x_p + 1.2x_c, \quad (3.1)$$

$$Depth = Length \times \frac{D}{L}, \quad (3.2)$$

$$Breadth = Length \times \frac{D}{L}, \quad (3.3)$$

With these equations in mind, the fuselage can therefore be estimated, with the results shown in Table 3.2.

**Table 3.2**

*This table shows the estimated values for the fuselage.*

Length (m)	Breadth (m)	Depth (m)
16.62	2.2	2.2

These values can then be used as a basis when the fuselage design is considered later in the design process. The fuel fraction, however, can now be calculated by the following equation:

$$ff = 1.046 - e^{-0.3504 \times SFC \times \frac{Range}{\sqrt{AR}}}, \quad (3.4)$$

When this equation is applied to the values found in Table 3.1, the fuel fraction obtained is 0.131, rounded to 3 decimal places. This means that roughly 13% of the aircraft's weight will be taken up by only the fuel needed to fly, assuming maximum takeoff weight. Similarly, the payload weight can be found by the equation:

$$W_p(N) = g(x_p \times 90 + x_c \times 500), \quad (3.5)$$

Therefore, the payload weight is found to be 24.92kN. Next, the structural weight can be found, which uses the previously defined parameters for fuselage length, breadth and depth. This means that when the fuselage design has been completed, the weights can be

re-estimated to find a more precise maximum takeoff weight. Structural weight is found by the following equation:

$$W_s(N) = 0.15503 \left( L \times \frac{B \times D}{2} \right)^{1.3909} \quad (3.6)$$

This means that the structural weight was found to be 23.15kN. Finally, the maximum takeoff weight can now be determined by the following equation:

$$W_{to}(kN) = \frac{5 + W_p + W_s}{0.8 - ff} \quad (3.7)$$

This means that the aircraft's maximum takeoff weight is 84.59kN, which definitely falls within the requirements of EASA-Part 25 to be considered a large aeroplane (greater than 5700kg). Ultimately, this is a good design weight for the aircraft as it falls at the lower end of all the aircraft previously discussed in the market survey, while still being able to carry a sufficiently large payload weight.

### 3.2 Centre of Gravity

Once the aircraft's wings, fuselage, and weights have been estimated, balancing the centre of gravity is an excellent way to confirm whether the design choices up to that point were suitable. In addition, EASA Part 25 sets out several key parameters in order for the aircraft to be certifiable, most notably that the centre of gravity's position must be no more than 50% of the mean aerodynamic chord or less than 25% of the mean aerodynamic chord. Furthermore, this must be true in both standard and extreme loading conditions to ensure the flight crew can fly the aircraft with relative ease.

With this in mind, while noting the aircraft's initial geometry and layout, the centre of gravity positions can be calculated; this was completed using the moment method, with the reference point taken as the aircraft's nose.

$$X_{CG} = \sum \left( \frac{m_x x}{m_{Total}} \right), \quad (3.8)$$

Where  $m_x$  is the mass of a specific component and  $x$  is the distance of that component from the datum.  $m_{Total}$  is the total mass of all components onboard the aircraft.

Table 3.3 shows the values used to calculate  $X_{CG}$  assuming maximum fuel and payload. The values given for  $m_x$  are as fractions of the aircraft's maximum takeoff weight.

**Table 3.3**

*A table showing the weight fraction of all components onboard the aircraft and their respective position relative to the nose of the aircraft.*

Component	$m_x$ (Kg)	$x$ (m)
Wing	0.072472	7.29
Fuselage	0.17343	6.65
Tailplane	0.01462	15.08
Fin	0.01389	14.35
Main Undercarriage	0.03586	8.04
Nose Undercarriage	0.01206	2.97
Flying Controls	0.01715	7.11
Engine Pod	0.01833	5.97
Engine Installed	0.10689	5.55
Airframe	0.14	8.31
Fuel	0.13094	7.17
Payload	0.23256	5.84

Therefore, when applying Equation 3.8, the centre of gravity position is found to be 6.93m from the aircraft's nose.

At this stage, it's important to consider how some components' mass will change in flight while others will not. For example, the mass of the aircraft's fuel tanks will decrease during the flight as fuel is burned. However, an aircraft's undercarriage will remain at a constant weight throughout the flight. This is an important consideration to make when tweaking component positions in order to gain a suitable  $X_{CG}$  position.

Once the position of the centre of gravity is known, relative to the aircraft's nose, it is

vital to find the position of the centre of gravity in terms of the aircraft's mean aerodynamic chord (MAC). This can be done using the following relationship:

$$X_{CG_{MAC}} = \frac{X_{CG} - X_{MAC_{LE}}}{MAC}, \quad (3.9)$$

Where  $X_{MAC_{LE}}$  is the position of the leading edge of the mean aerodynamic chord and  $MAC$  is the length of the mean aerodynamic chord. Therefore, the position of the centre of gravity, as a fraction of the mean aerodynamic chord, is given to be 0.31. This value is within the limits that were previously discussed. Yet, this calculation was only completed for one loading condition, maximum fuel capacity and maximum payload.

To remain completely compliant with EASA Part-25, this process was repeated for several loading conditions, specifically decreasing fuel by 10% until there was no fuel left for five different payload configurations. The output for these calculations are plotted on the graph shown in Figure 3.1.

**Figure 3.1***The change in CG Position as Fuel Load Decreases*

Figure 3.1 ultimately shows that no matter the aircraft's loading configuration, the CG position remains within the acceptable limits imposed in EASA Part-25. This means that the aircraft has been successfully balanced and that the initial aircraft configuration is acceptable and can be built on in further elements, such as the design of the tailplane and undercarriage.

Throughout the design process, the CG was constantly tweaked. For example, after completing the fin and tailplane design, more accurate values for tailplane weight and position could be used and implemented in the CG balancing method. This meant that the overall aircraft balancing was constantly being tweaked by slightly moving components with constant weight throughout the flight. The values discussed in this report represent the final values once the design had been completed.

### 3.3 Environmental Control Systems

Environmental Control systems are crucial to ensure that passengers remain not only comfortable but alive during extended periods at high altitudes. Of course, the aircraft that is being designed is primarily for the transportation of equipment and supplies, but even then, they must be kept at a regulated temperature to ensure that they are free from damage when ready for use. While EASA does not have any particular requirements for environmental control systems, most modern aircraft maintain approximately 10 cubic feet per minute per passenger. This will be a design goal that is kept in mind throughout this process.

The following two subsections are dedicated to evaluating the fuselage's skin temperature in various conditions so that heat loading can be calculated for the aircraft in those same conditions.

#### 3.3.1 Airfield Condition

When aircraft are on the ground at an airfield, the cabin temperature will be maintained to create a comfortable environment. For the purposes of these calculations, two extreme conditions will be considered: a hot day ( $45^\circ$ ) without wind and a cold day ( $-20^\circ$ ) without wind. These two conditions will see the environmental control systems work at their hardest, as in the presence of wind, some natural cooling will occur due to decreased fuselage skin temperature. The following parameters are used in this set of calculations: These

**Table 3.4**

*This table shows the parameters used when calculating the skin temperature on hot and cold days*

Skin Temperature	$T_s$
Cabin Temperature	$T_c$
Ambient Temperature	$T_1$
Heat Transfer Coefficient	$U_f$

parameters are then applied to Equations 3.10 and 3.11 for a cold and hot day, respectively,

aircraft. The mathematical expression for this involves Reynold's analogy between heat transfer and skin friction, which is expressed in terms of the Stanton Number,  $S_t$ , as seen in Equation 3.12.

$$S_t = \frac{q}{\rho u C_p (T_r - T_s)}, \quad (3.12)$$

Where  $q$  is equal to the heat transfer per unit area of skin and  $T_r$  is the recovery temperature of the skin surface. The equation for  $T_r$  is seen in Equation 3.13. In addition,  $q$  can be expressed by Equation 3.14, where  $S_f$  is the fuselage surface area where heat transfer takes place.

$$T_r = T_1 (1 + 0.18 M^2), \quad (3.13)$$

$$q = \frac{Q}{S_f} = U_f (T_s - T_c), \quad (3.14)$$

This means that an equation for  $T_s$  can be constructed, assuming that the Stanton number can be evaluated differently. This is the case, as the Stanton number can be found using the relationship between the average skin friction coefficient ( $C_F$ ) and the Prandtl number ( $\sigma$ ), which is normally taken as 0.72 in air, and is shown in Equation 3.15.

$$S_t = \frac{C_F}{2\sigma^{\frac{2}{3}}}, \quad (3.15)$$

The average skin friction coefficient can be found using the Prandtl-Schlichting relationship (Equation 3.17), using the Reynold's number based on fuselage length ( $R_L$ ), which is given by Equation 3.16.

$$R_L = \frac{\rho u L}{\mu}, \quad (3.16)$$

$$C_F = 0.455(1 - 0.1M)(\log_{10}R_L)^{-2.58}, \quad (3.17)$$

Finally, this means that the equation for  $T_s$  in terms of the Stanton Number can be constructed, as shown in Equation 3.18.

$$T_s = \frac{S_t \rho u C_p T_r + U_f T_c}{U_f + S_t \rho u C_p}, \quad (3.18)$$

Therefore, considering a cruising speed of 140 meters per second and a fuselage length of 16.62 meters,  $C_F$  can be calculated using Equation 3.17 and a value of 0.002143 is obtained. This means that the Stanton Number can be evaluated using Equation 3.15, and a value of 0.001334 is obtained. At a cruising altitude of twenty thousand feet, the ambient temperature is approximately  $-27.1^\circ\text{C}$ , therefore, using Equation 3.13, the recovery temperature is found to be  $-28.05^\circ\text{C}$ . Finally, this means that the skin temperature can be obtained using Equation 3.18, assuming the value of  $T_c$  is cool at approximately  $18^\circ\text{C}$ , the value of the skin temperature is  $-27.06^\circ\text{C}$ .

### 3.3.3 Calculating Heat Load

Now that the skin temperature values have been obtained in the three different conditions, the heat load of the Environmental Control system can be calculated for each. Heat loading,  $Q$ , is given by Equation 3.19, where  $N_p$  is the number of passengers (7),  $\frac{D}{L}$  is the drag to lift ratio,  $\frac{W_p}{W}$  is the payload weight to weight ratio, and  $V$  is the cruise speed.

$$Q = U_f S_f (T_s - T_c) + 450 \times 2.2 + 4.75 N_p (39.8 - T_c) + 0.001 \frac{D}{L} \frac{W_p}{W} V W_p, \quad (3.19)$$

Table 3.5 shows the various heat loads and their respective skin temperatures.

**Table 3.5**

*This table shows the heat loads for different skin temperatures and conditions*

Skin Temperature $T_s$ ( $^{\circ}\text{C}$ )	Heat Load $Q$ (W)	Condition
-1.44	-5151.02	Airfield Cold
50.29	11943.91	Airfield Hot
-27.06	-11170.12	Cruising

With the values of heat loading known, the mass flow rate for both the environmental control system ( $\dot{m}_{ecs}$ ) and the recirculation system ( $\dot{m}_r$ ) can be obtained by Equations 3.20 and 3.21, respectively.

$$\dot{m}_{ecs} = \frac{Q}{C_p(T_c - T_{ecs})}, \quad (3.20)$$

$$\dot{m}_r = \frac{T_{in}\dot{m}_{ecs} - \dot{m}_{ecs}T_{ecs}}{T_c - T_{in}}, \quad (3.21)$$

Table 3.6 shows the various mass flow rates, for each of the 3 conditions.

**Table 3.6**

*This table shows the different mass flow rates in different conditions.*

$\dot{m}_{ecs}$ (kg/s)	$\dot{m}_r$ (kg/s)	Condition
0.109	0.025	Airfield Cold
0.914	0.552	Airfield Hot
0.236	0.047	Cruising

These values are acceptable for the heat loading of the aircraft's environmental control system, and the values for mass flow rate are acceptable, enough air is being provided to the cabin in all phases of flight, and the percentage of air being recirculated is less than 45% in all conditions, thus meeting the necessary certification requirements apart of EASA Part-25.

## **4 Secondary Tasks**

The following tasks, aircraft drag prediction and tail and fin design, were assigned to the author in a secondary capacity. This means that it was the author's duty to confirm and corroborate the primary's decisions by repeating calculations to ensure that their decisions made sense and met the necessary certification requirements outlined in EASA Part-25.

### **4.1 Aircraft Drag Prediction**

When mathematically predicting the drag of the aircraft, the drag area methods are employed to find the drag induced by:

1. The wing,
2. The fuselage,
3. The nacelles.

In order to complete these calculations, a number of parameters are needed; these can be found in Table 4.1.

**Table 4.1**

*Table of values used to compute drag prediction at cruising altitude.*

Parameter	Mathematical Symbol	Value for our Aircraft
Airpseed	$V$	140
Altitude	$h$	7.62
Wing Area	$S$	33.836
Thickness to Chord Ratio	$t_c$	0.18
Quarter Chord Sweep	$\Lambda_{\frac{1}{4}}$	5
Fuselage Length	$l_f$	16.62
Fuselage Breadth	$b_f$	2.2
Fuselage Depth	$d_f$	2.2
Number of Engines	$n_e$	2
Engine Power	$P$	1945
Engine $k_i$	$k_i$	1
Maximum Takeoff Weight	$W_{TO}$	8.6
Empennage Factor	$C_e$	1.24
Undercarraige Factor	$C_{UC}$	1.08
Compressibility Increment	$c$	0.0005
Drag induced by flaps at takeoff	$\Delta C_{Dof}$	0.03156
Drag induced by flaps at landing	$\Delta C_{Dla}$	0.033708

It is important to remember the fact that these values would calculate drag at cruising speed only. By modifying the values for airspeed and altitude, drag could be predicted in different phases of flight. This will be completed, and the different values used for airspeed and altitude will be shown in Table 4.2.

**Table 4.2**

*The different values of airspeed and altitude used to compute drag in different phases of flight.*

Condition	Altitude (km)	Airspeed (m/s)
<b>2000ft</b>	0.6096	82
<b>Gear Down</b>	0.6096	77
<b>Landing</b>	0.3048	72
<b>Takeoff</b>	0.3048	72

Equations 4.1 (wing drag area), 4.2 (fuselage drag area), 4.3 (nacelle drag area) show how the different drag areas can be calculated based on the parameters detailed in Table 4.1, whereas Equation 4.4 shows how to find the overall drag area of the aircraft.

$$(C_D S)_w = 0.0054(1 + 3t_c \times \cos^2(\Lambda_{\frac{1}{4}})), \quad (4.1)$$

$$(C_D S)_f = 0.0031l_f(b_f + d_f), \quad (4.2)$$

$$(C_D S)_p = 0.1k_i \frac{P}{717.2P^{0.168}n_e}, \quad (4.3)$$

$$C_D S = (47Re^{-0.2})C_{UC}(C_e((C_D S)_w + (C_D S)_f) + (C_D S)_p), \quad (4.4)$$

Once these equations have been applied to the values previously discussed in Tables 4.1 and 4.2, values for the coefficients of drag can be calculated, the Equation for clean drag ( $C_{DO}$ ) can be seen in Equation 4.5, the equation for drag due to undercarriage deployment ( $(C_{DO})_{uc}$ ) can be seen in Equation 4.6 and finally drag due to flap extension at takeoff

$((C_{DO})_{to})$  and landing  $((C_{DO})_{la})$  can be seen in Equations 4.7 and 4.8 respectively.

$$C_{DO} = \frac{C_D S}{S} + c, \quad (4.5)$$

$$(C_{DO})_{uc} = (0.095 + 1 * 0.063) \left( \frac{W_{TO}^{0.785}}{S} \right), \quad (4.6)$$

$$(C_{DO})_{to} = C_{DO} + (C_{DO})_{uc} + \Delta C_{Dof}, \quad (4.7)$$

$$(C_{DO})_{la} = C_{DO} + (C_{DO})_{uc} + \Delta C_{Dla}, \quad (4.8)$$

Now that all the equations have been defined, the coefficient of drag can be calculated in many different conditions, the results of which are shown in Table 4.3.

**Table 4.3**

*The table shows the different drag coefficients at five different phases of flight.*

Condition	Altitude (km)	Airspeed	Gear	Flaps	Drag
<b>Cruise (25000ft)</b>	7.62	140	No	No	0.03109
<b>2000ft</b>	0.6096	82	No	No	0.030617
<b>Gear Down</b>	0.6096	77	Yes	15	0.089991
<b>Landing</b>	0.3048	72	Yes	45	0.090253
<b>Takeoff</b>	0.3048	72	Yes	30	0.088105

These values are sufficiently close to those calculated by the primary designer for the aircraft drag prediction. This process cannot comment on the choices made by the primary designer as this element of the design process is purely analytical, which attempts to identify if the aircraft performs with an acceptable drag component. However, this process can

reasonably say that the primary designer performed the calculations correctly and to a high degree of accuracy as the values obtained by the independent methods are within a reasonable degree of accuracy of one another.

## 4.2 Tail and Fin Design

## 4.3 Airfield Performance

Similarly to Chapter 4.1, when assessing airfield performance in the role of a secondary, the goal is to not comment on design choices made as no unique decisions are made at this phase of design. Instead, the performance of the aircraft is estimated based on its design values by a numerical analysis. The goal of said analysis is to obtain values for:

1. Aircraft Landing distance, in meters,
2. Aircraft takeoff distance, in meters,
3. Aircraft climb out angle, in degrees, for an all engine case and an engine failure case.

Furthermore, it is important that these parameters comply with EASA Part-25 regulations for airfield performance. In particular, EASA states that in an engine failure situation, the minimum climb out angle for a large aeroplane is  $1.38^\circ$ . This design phase is the final checkpoint for the aircraft designed for this project and will ultimately inform the design team if the design objectives have been met. After some mathematical analysis, the takeoff speed for the aircraft is found to be 44m/s and is found by Equation 4.X.

$$V_{TO} = \sqrt{\frac{2W/S}{\rho(C_L)_{max}}}, \quad (4.9)$$

Also, the takeoff field length is found to be 339m, with an abort takeoff distance of 204m. This means that the speed for  $V_1$  will be set so that there is always a minimum distance of 204m so that the aircraft can stop safely. In the event of an engine failure past the point of  $V_1$ , the takeoff distance will naturally increase, in this case to a distance of 892m, which takes the value of the Balanced Field Length. This is the minimum safe distance that an aircraft can take off at as there should always be preparations for an aborted takeoff or engine failure past the point of no return. These values are sufficiently close to those calculated by the primary

designer at this stage, and therefore, there is a high level of confidence that they are the true, correct values for the aircraft.

Importantly, the climb-out angle for the aircraft was also calculated, both for an engine failure and for normal takeoff conditions. In normal takeoff conditions, the climb out angle was calculated to be  $12^\circ$ , whereas in an engine failure condition, the climb out angle was found to be  $1.53^\circ$ . Importantly, these values are both sufficiently close to those calculated by the primary designer but also completely comply with EASA Part-25 requirements for large aeroplanes.

Finally, the landing distance, with included factor of safety, was found to be 1005m. Again, this value is sufficiently close to the one calculated by the primary designer.

There is a high level of confidence in the calculated airfield performance of the aircraft as the primary and secondary designers have made similar conclusions based on the values obtained. While the climb-out angles are very good in both conditions, the landing and takeoff distance values are slightly higher than ideal, considering the aircraft's goal was to operate to and from damaged or makeshift airfields in hazardous areas. If given the ability to complete further study, the secondary designer's recommendation would be to tweak certain aircraft parameters, such as increasing the coefficient of lift due to flaps extended at takeoff and landing. This is because Figure 4.X shows an inverse exponential relationship between  $C_L$  and Balanced Field Length; as  $C_L$  increases, the Balanced Field length decreases.

**Figure 4.1**

*The relationship between balanced field length and  $C_L$ .*
